Abstract

Datalog may be considered either an unusually powerful query language or a carefully limited logic programming language. Datalog is declarative, expressive, and optimizable, and has been applied successfully in a wide variety of problem domains. However, most use-cases require extending Datalog in an application-specific manner. In this paper we define Datafun, an analogue of Datalog supporting higher-order functional programming. The key idea is to track monotonicity with types.

Categories and Subject Descriptors F.3.2 [Logics and Meanings of Programs]: Semantics of Programming Languages

Keywords Prolog, Datalog, logic programming, functional programming, domain-specific languages, type theory, denotational semantics, operational semantics, adjoint logic

1. Introduction

The phrase “declarative programming” is as popular as it is ambiguous, with seemingly hundreds of disparate senses in which it is used. However, two of those usages stand out for popularity: both functional and logic programming languages are generally deemed declarative languages. Despite this shared epithet, the logic and functional programming traditions have largely evolved independently of one another (with a few honorable exceptions such as Mercury (Somogyi et al. 1994), Curry (Antoy and Hanus 2010) and Kanren (Friedman et al. 2005)). This could be seen as an occasion for sorrow, but we prefer to view it as an opportunity: as functional language designers, we can look to logic languages to discover new ideas to steal.

A Prolog program can be understood as a collection of logical axioms formulated as Horn clauses (i.e., first-order formulas of the form \( \forall x. P_1 \land \ldots \land P_n \rightarrow Q \), where \( P_i \) and \( Q \) are atomic formulas). Execution of a Prolog program can be understood as running a proof search algorithm on these clauses to figure out whether a particular formula is derivable or not.

In other words, functional and logic programming languages embody the Curry-Howard correspondence in two different ways. In a functional language, types are propositions, terms are proofs, and program evaluation corresponds to proof normalization. On the other hand, for logic programming languages, terms are propositions, and program evaluation corresponds to proof search.

Since proof search is in general undecidable, designers of logic programming languages must be careful both about the kinds of formulas they admit as programs, and about the proof search algorithm they implement. Prolog offers a very expressive language — full Horn clauses — and so faces an undecidable proof search problem. Therefore, Prolog specifies its proof search strategy: depth-first goal-directed/top-down search. This lets Prolog programmers reason about the behaviour of their programs; however, it also means many logically natural programs fail to terminate. Notoriously, transitive closure calculations are much less elegant in Prolog than one might hope, since their most natural specification is best computed with a bottom-up (aka “forwards chaining”) proof search strategy.

This view of Prolog suggests other possible design choices, such as restricting the logical language so as to make proof search decidable. One of the oldest such variants is Datalog (Gallaire and Minker 1978), a subset of Prolog satisfying three restrictions:

1. Programs must be constructor-free: only atomic terms and variables are permitted to appear as arguments to predicates. This ensures that deduction will not introduce terms that do not occur in the source of the program.
2. Clauses are range-restricted: all variables in the consequent (head) of a clause must also occur positively in its premises (body).
3. Programs are limited to stratified negation: the negation of a predicate may be used in a definition only if it has already been fully defined. That is, within the recursive definition of a predicate, it cannot be used in negated form.

These restrictions make Datalog Turing-incomplete: all queries are decidable. As functional programmers are well aware, though, there is power in restraint: for example, in a total functional language, the compiler may switch between strict and lazy evaluation at will. Similarly, in Datalog decidability means that implementations are free to use forwards chaining, and so can easily support queries (like reachability and transitive closure) which are difficult to implement in ordinary Prolog.

Over the last decade or so, this freedom has been put to good use, with Datalog appearing at the heart of a wide variety of applications in both research and industry. For example, Whaley and Lam (Whaley et al. 2005) implemented pointer analysis algorithms in Datalog, and found that they could reduce their analyses from thousands of lines of C code to tens of lines of Datalog code, while retaining competitive performance. Semmle has developed the .QL language (de Moor et al. 2007) based on Datalog for analysing source code (which was used to analyze the code for NASA's Curiosity Mars rover), and LogicBlox has developed the LogiQL (Aref et al. 2015) language for business analytics. The Boom project at Berkeley has developed the Bloom language for distributed programming (Alvaro et al. 2011), and the Datomic cloud database (Hickey et al.) uses Datalog...
We give the core syntax of Datafun in Figure 1. Datafun is a simply-typed λ-calculus extended in four major ways:

1. We add a type of finite sets, \{A\}.

2. We add a type of monotone functions, A \rightharpoonup B. Consequently Datafun has two flavors of variable: ordinary variables, which we call discrete, and monotone variables. We write discrete variables in script and monotone variables in bold.

In order for “monotone” to have meaning, our types are implicitly partially ordered:

- Booleans 2 are ordered false < true.
- Natural numbers \(\mathbb{N}\) have the usual order: 0 < 1 < 2 < ...
- We have no particular use-case for comparing strings \text{str} in this paper, so we order them discretely: \(a \leq b\) iff \(a = b\).
- Pairs and functions are ordered pointwise:
  - \((a, x) \leq (b, y)\) iff \(a \leq b \land x \leq y\)

\(\Gamma\) := \(\cdot | \Gamma, x : A\)

\(e\) := \(\text{x} \times \text{x} | \lambda x. e | \lambda x. e | e e\)

terms

\(\text{in}\) \(\epsilon\) \(\in\) \(\subseteq\)

g\(x\) \(\ll\) \(\geq\)

\(\text{fix x is e if x \leq e}\)

Figure 1. Syntax of core Datafun

- \(f \leq g\) iff \(\forall x. f x \leq g x\)
- Sum types are ordered disjointly: \(in_1 a \leq in_1 b\) iff \(a \leq b\), but \(in_1 a\) and \(in_2 b\) are never comparable.
- Sets are ordered by inclusion: \(a \leq b\) iff \(a \subseteq b\).

3. We add a term \(\text{fix x is e}\) denoting the least fixed point of the monotone function \((\lambda x. e)\). This is computed (modulo optimizations) by iteration, starting from the smallest value of the desired type and halting once a fixed point is found. This strategy constrains the types of fix terms in several ways:

- The type must have a smallest value. We enforce this using semilattice types (see items 1, 2 below).
- The type must support equality tests, to determine when a fixed point has been reached. We call a type supporting equality tests an eqtype.
- To ensure termination, the type must have finite height. We conservatively approximate this property by limiting fix to finite types.

In summary, fix may only be used at finite semilattice eqtypes.

4. Generalizing the empty set \(\emptyset\) and union \(\cup\), we identify a subset of types that have a least element \(\epsilon\) and a least upper bound operator \(\lor\). We call these semilattice types and denote them by the metavariables L, M.

Semilattice types serve two purposes. First, as already mentioned, they guarantee the presence of a least element, needed to compute fix terms.

Second, they provide a natural eliminator for sets. Given \(e_1 : A\), we write \(\lor\{x < e_1\} e_2\) for the least upper bound, over all elements \(x < e_1\), of \(e_2\), provided \(e_2\) has some semilattice type L.

The height of a poset is the cardinality of its largest chain (totally-ordered subset).

2 Technically, the partial orderings on these types form join-semilattices with a least element. For brevity’s sake, we call these structures simply “semilattices.”

\end{cases}

Figure 3. Pattern matching expansion

If \(e_2\) is a set, for example, this provides the set type’s monadic “bind” operation. For example, \(\forall (x \in \{1, 2, 3\}) \left\{10 \cdot x, x^2\right\}\) denotes the set \(\{1, 4, 9, 10, 20, 30\}\).

3. Examples

For purposes of these examples, we use a simple Haskell-like syntax for top-level type and function definitions. We also permit ourselves infix notation, let-binding, \(n\)-ary tuples, \(n\)-ary sum types with named constructors, and a restricted form of pattern-matching (including non-linear patterns), and additional syntax sugar given in Figures 2 and 3. These figures also show how to expand the sugar into our core language. Full expansion for case-analysis is complicated, so we include only the fragment for expressions of the form \(\text{case } e_1 \text{ of } p \to e_2; \ _ \to e_3\), as that is all we use in this paper. All of these conveniences are supported (with slightly different concrete syntax) in our implementation.

For clarity, we set the names of top-level variables in sans-serif; discrete variables in script (for long variable names); and monotype variables in \textit{bold}. Although Datafun as presented does not have polymorphism, we give our examples their most general possible type schemes.

3.1 Filtering, Mapping, and Cross Products

Armed with the syntactic sugar given in Figure 2 \footnote{Figure 2. Syntax sugar.} basic set operations such as map, filter, and cross-product are easy first examples:

\begin{align*}
\text{map} & : (A \to B) \to \{a \in A \mid \text{map } f A = \{f x \mid x \in A\}\} \\
\text{map f} A & = \{f x \mid x \in A\} \\
\text{filter} & : (A \to B) \to \{a \in A \mid \text{filter } f A = \{x \mid x \in A, f x\}\} \\
\text{filter f} A & = \{x \mid x \in A, f x\} \\
\text{filter } (x) & : \{a \in A \mid \text{filter } f A = \{x \mid x \in A \times B\} \\
A \times B & = \{(a, b) \mid a \in A, b \in B\}
\end{align*}

Worth noting here are the subtleties of monotonicity typing. For example, map is not monotone in its function argument, while filter is. Recalling that sets are ordered by inclusion, this is straightforward enough — observe, for example, that:

\begin{align*}
\text{map } & (\leq 0) \to \{0, 1\} \\
\text{filter } (\leq 0) \to \{0, 1\} & \subseteq (\leq 0) \to \{0, 1\}
\end{align*}

However, it is perhaps unclear how Datafun’s type system “knows” filter is monotone in \(f\). In brief, Datafun knows that application \((f x)\) is monotone in the function, and moreover, testing a boolean guard \((f x)\) in a set-comprehension such as \(\{x \mid x \in A, f x\}\) is monotone in the guard expression. The full explanation is in Section 4.

3.2 Equality, Membership, and Intersection

So long as the type of a set’s elements supports equality, we can test whether the set contains a value \(x\) as follows:

\begin{align*}
(\in) & : A \to \{\downarrow A\} \to 2 \\
\ x \in A & = \forall (y) \in A \mid x = y \\
\end{align*}

The expression \(\forall (y) \in A \mid x = y\) takes the least upper bound, at boolean type, for every \(y \in A\), of the value of \(x = y\). Since booleans are ordered \textit{false < true}, “least upper bound” is simply logical disjunction!

Similarly, we can define set intersection by testing for equality:

\begin{align*}
\uplus & : (\downarrow A \to \downarrow A) \to (\downarrow A \to \downarrow A) \\
A \uplus B & = \{x \mid x \in A \land y \in B, x = y\}
\end{align*}
However, explicitly binding multiple variables only to test for equality can become tedious, so we support a form of equality patterns. The grammar of patterns includes the form `c e`, which means the term at that position equals the value of e. So we can indicate that a pattern must have an equal value at different positions by binding the first one to a variable x, and then marking later positions with a `!x`. Now, the intersection can be written as:

\[(\cap) : \{A\} \rightarrow \{\{A\} \rightarrow \{A\}\} \]

\[A \cap B = \{x | x \in A, x \in B\}\]

Since `!x` implies the use of an equality test, the condition that the set's element type support equality remains in force.

### 3.3 Composition of Relations

One extremely useful operator it is convenient to define using nonlinear pattern matching is composition of finite relations (that is, sets of pairs):

\[\bullet : \{A \times B\} \rightarrow \{B \times C\} \rightarrow \{A \times C\}\]

\[R \circ S = \{\langle a, c \rangle | \langle a, b \rangle \in R, \langle b, c \rangle \in S\}\]

This already demonstrates a capability Datafun has that Datalog does not: defining operators over relations. A Datalog program defining binary predicates `r` and `s` which wished to compose those predicates would have to define a new top-level predicate:

\[r(X,Y) ::= (\ldots)\]

\[s(X,Y) ::= (\ldots)\]

\[rs(A,C) ::= r(A,B) \circ s(B,C)\]

In Datafun, we simply define `\bullet` and use it inline as needed. We shall see the use of this in later examples.

### 3.4 Transitive Closure

Consider the following Datalog program, authored perhaps by a J.R.R. Tolkien aficionado wishing to trace the genealogies of their favorite work, The Silmarillion:

\[\text{parent}(\text{earendil}, \text{elrond}).\]

\[\text{parent}(\text{elrond}, \text{arwen}).\]

\[\text{ancestor}(X, Y) ::= \text{parent}(X, Y).\]

\[\text{ancestor}(X, Z) ::= \text{ancestor}(X, Y), \text{ancestor}(Y, Z).\]

This defines a binary parent relation, along with its transitive closure, ancestor. The Datafun equivalent is:

\[\text{data} \text{person} = \text{EARENDIL} \mid \text{ELROND} \mid \text{ARWEN}\]

\[\text{parent}, \text{ancestor} : \{\text{person} \times \text{person}\}\]

\[\text{parent} = \{(\text{EARENDIL}, \text{ELROND}), (\text{ELROND}, \text{ARWEN})\}\]

\[\text{ancestor} = \text{fix} X \text{ is parent} \vee (X \bullet X)\]

The type person represents the domain of our parent and ancestor relations. parent is simply a list of parent-child pairs. ancestor is where the action is at: since the Datalog predicate ancestor is defined recursively, ancestor is defined as a least fixed point — in this case, of the the equation

\[X = \text{parent} \vee (X \bullet X)\]

Informally, we may read this as stating that a pair is in X if it is in either parent or the composition of X with itself. This requires that X contain the transitive closure of parent. And since we take the least fixed point of this equation, ancestor contains exactly the transitive closure of parent. Voilà!

#### 3.4.1 Transitive Closure with an Upper Bound

The preceding explanation glosses over a critical requirement: fix may only be used at finite semilattice eqtypes. ancestor has type \((\text{person} \times \text{person})\). Does this suffice? It’s certainly a semilattice, since it’s a set type. Since person is effectively a sum of units, it supports equality, and sets and products of eqtypes are themselves eqtypes. Likewise, person is finite, and products and sets of finite types are themselves finite.

So we are in the clear, but in general the restriction of fix to finite types can be quite limiting. So Datafun provides a more general way to take a fixed-point: specify an upper bound which the fixed point may not exceed. For this we write \((\text{fix} X \leq e_T) = e\), where \(e_T\) is our upper bound.

Suppose, for example, we represent our \textit{dramatis personae} as strings (an infinite type). We may write:

\[\text{persons} : \{\text{str}\}\]

\[\text{parent}, \text{ancestor} : \{\text{str} \times \text{str}\}\]

\[\text{parent} = \{(\text{"earendil"}, \text{"elrond"}), (\text{"elrond"}, \text{"arwen"})\}\]

\[\text{ancestor} = \text{fix} X \leq (\{\text{persons} \times \text{persons}\}) \text{ is parent} \vee (X \bullet X)\]

Instead of a person type, we have persons set, which we use to construct an upper bound on our fixed-point: \((\{\text{persons} \times \text{persons}\})\). the complete binary relation. Since all strings in parent are in persons, the transitive closure of parent cannot exceed the bound. However, this invariant is left to the programmer to check. What if a sloppy programmer should mistakenly include a person in parent not present in persons? More generally, what if the fixed point \((\text{fix} X \leq e_T) = e\) is trying to compute exceeds \(e_T\)? Or indeed, no such fixed point exists?

In that case, the value of \((\text{fix} X \leq e_T) = e\) is clamped to the upper bound \(e_T\). This ensures Datafun programs terminate even in the presence of sloppy programmers, and although they may not have the value you expect, that value is at least predictable.

### 3.4.2 Generic Transitive Closure

Thus far we have only considered taking the transitive closure of a relation we have already defined. But consider: for any eqtype \(A\), we may write:

\[\text{trans} : \{A \times A\} \rightarrow \{A \times A\}\]

\[\text{trans} E = \text{fix} X \text{ is } E \lor (X \bullet X)\]

Similarly, for any eqtype \(A\), we may write:

\[\text{trans} : \{A\} \rightarrow \{A \times A\} \rightarrow \{A \times A\}\]

\[\text{trans} V E = \text{fix} S \leq (V \lor S) \text{ is } E \lor (S \bullet S)\]

In this way, we can abstract away from choice of underlying relation and define transitive closure generically. Using functions as a means of abstraction is of course familiar and unremarkable to functional programmers, but it is simply not possible in Datalog.

### 3.5 CYK Parsing

Parsing can be understood logically, with a parse tree representing a proof that a certain string belongs to a language described by a context-free grammar. As a result, it is possible to formulate parsing in terms of proof search\(^3\). One of the simplest algorithms for parsing context-free grammars is the Cocke-Younger-Kasami (CYK) algorithm for parsing with grammars in Chomsky normal form\(^4\). Given a grammar \(G\), we begin by introducing a family of predicates (sometimes called \textit{facts} or \textit{items}) \(A(i,j)\), with one \(A\) for each nonterminal, and \(i\) and \(j\) representing indices into a string. Given a word \(w\), we write \(w[i..n]\) for the \(n\)-element substring of \(w\).

\(^3\)In Chomsky normal form, each production is of the form \(A \rightarrow B \cdot C\) or \(A \rightarrow \bar{A}\), with \(A, B, C\) ranging over nonterminals, and \(\bar{A}\) over strings of terminals.
we can write down the
with strings. The
iter
text

chart
then taking a set of facts
produce.
longest text
and a grammar
boundedly. To ensure termination, we construct a set
bound
to
beginning at position \( i \). Then, we can specify the CYK algorithm
with the following two inference rules:

\[
\begin{align*}
B(i, j) & \quad C(j, k) & \quad (A \rightarrow B C) \in G \\
A(i, k) & \quad (A \rightarrow \alpha) \in G & \quad w[i, n] = \alpha
\end{align*}
\]

Then, the predicate \( A(i, j) \) means that \( A \) is derivable from the
substring of \( w \) running from \( i \) to \( j \), and so the whole word \( w \) is derivable
from the start symbol \( S \) if \( S(0, \text{length } w) \) is derivable.

In Datalog, this rule-based description of the algorithm can be
transliterated almost directly into code. We begin by introducing a
few basic types.

\[
\begin{align*}
type & \quad \text{sym} = \text{str} \\
data & \quad \text{rule} = \text{STRING str | CONCAT sym sym} \\
type & \quad \text{grammar} = \{\text{sym} \times \text{rule}\} \\
data & \quad \text{fact} = \text{sym} \times \mathbb{N} \times \mathbb{N}
\end{align*}
\]

The \( \text{sym} \) type is a type synonym representing nonterminal names
with strings. The \( \text{rule} \) type is the type of the right-hand-sides of
productions in Chomsky normal form – either a string, or a pair
of nonterminals. A grammar is just a set of productions – a set of
pairs of nonterminals paired with their rules. The \( \text{fact} \) type is the
representation of atomic facts derived by the CYK inference
system – they are triples of the rulename, the start position, and the
end position.

With these types in hand, we can write the CYK algorithm as a
fixed point computation. In fact, it is enough to break it into two
two pieces, by first defining the function whose fixed point we take. So
we can write down the \( \text{iter} \) function, which represents one step of
the fixed point iteration.

\[
\begin{align*}
\text{iter} & : \text{str} \rightarrow \text{grammar} \xrightarrow{+} (\text{fact}) \xrightarrow{+} (\text{fact}) \\
\text{iter text G chart} & = \\
& \quad \{(a, i, k) | (a, \text{CONCAT } b \ c) \in G, \\
& \quad (b, i, j) \in \text{chart}, \\
& \quad (c, j, k) \in \text{chart}\} \\
& \quad \text{OR} \{(a, i, i + \text{length } s), \\
& \quad (a, \text{STRING } s) \in G, \\
& \quad i \in \text{range } 0 (n - \text{length } s), \\
& \quad s = \text{substring } i (i + \text{length } s)\}
\end{align*}
\]

This function works by taking a string \( \text{text} \) and a grammar \( G \),
and then taking a set of facts \( \text{chart} \), and taking a union. The first clause
is a set comprehension, saying that we return \( (a, i, k) \) if \( (b, i, j) \)
and \( (c, j, k) \) are in \( \text{chart} \) – this corresponds to applications of the
first rule. The second clause corresponds to the second rule above,
saying that \( (a, i, i + \text{length } s) \) is a generated fact if \( s \) is a substring
of \( \text{text} \) at position \( i \).

We can then use \( \text{iter} \) to implement the parse function.

\[
\begin{align*}
\text{parse} & : \text{str} \rightarrow \text{grammar} \xrightarrow{+} (\text{sym}) \\
\text{parse text G} & = \\
& \quad \text{let } n = \text{length text} \\
& \quad \text{bound} = \{(a, i, j) | (a, \_ ) \in G, \\
& \quad i \in \text{range } 0 n, \\
& \quad j \in \text{range } i n\} \\
& \quad \text{chart} = \text{fix } C \leq \text{bound} \text{ is iter text G C} \\
& \quad \text{in } (a | (a, \_ , \_ ) | n) \in \text{chart}
\end{align*}
\]

This function just takes the fixed point of \( \text{iter} \) – almost. Because
facts are triples \( \text{sym} \times \mathbb{N} \times \mathbb{N} \), sets of facts may in general grow
unboundedly. To ensure termination, we construct a set \( \text{bound} \) to
bound the sets of facts we consider in our fixed point computation,
by bounding the symbols to names found in the grammar \( G \), and
the indices to positions of the string. Since all of these are finite, we
know that the computation of \( \text{chart} \) as a bounded fixed point will
terminate. Then, having computed the fixed point, we can check
chart to see if \( (a, \_ , \text{length } \text{text}) \) is derivable.

There are three things worth noting about this program. First, it
is not expressible in Datalog. Because Datalog provides no way to
represent a grammar as a piece of data (it’s compound, not an atom),
there is simply no way in Datalog to express a generic parser taking
a grammar as an input. This demonstrates one of the key benefits
of moving to a functional language like Datalog.

Moreover, Datalog programs must be constructor-free, to ensure
all relations are finite. Primitives such as range and substring violate
this restriction (as relations, they are infinite); it is not immediately
obvious that Datalog programs extended with these primitives
remain terminating. Our use of bounded fixed-points to guarantee
termination is robust under such extensions; as long as all primitive
functions are total, Datalog programs always terminate.

Finally, having computed a set via a fixed point, we can test
whether or not an element is in that set or not – the ability to test for
negative information after the fixed point computation completes
corresponds to a use of stratified negation in Datalog.

3.6 Dataflow Analysis

In this section, we show how some simple dataflow analyses can be
expressed in Datalog. We begin with the types in these programs.

\[
\begin{align*}
type & \quad \text{var} = \text{str} \\
type & \quad \text{label} = \mathbb{N} \\
data & \quad \text{oper} = \text{EQ | LE | ADD | SUB | MUL | DIV} \\
data & \quad \text{atom} = \text{VAR var | NUM } \mathbb{N} \\
data & \quad \text{expr} = \text{ATOM atom | APPLY oper atom} \\
data & \quad \text{stmt} = \text{ASSIGN var expr | IF expr label label} \\
type & \quad \text{program} = \{\text{label } \times \text{stmt}\}
\end{align*}
\]

The basic idea is that we represent a program as a kind of control
flow graph. Each node of this graph has a label, which is a natural
number, and contains a statement of type stmt, which is either an
assignment of an expression (of type expr) to a variable (of type
var), or a conditional jump. A program is then just the set of nodes
– i.e., a set of label, statement pairs – with the invariant that the
relation is functional (i.e., if \((l, s)\) and \((l, s')\) are both in a program,
then \( s = s' \)).

In what follows, we use a few trivial functions whose definitions
are omitted for space reasons.

\[
\begin{align*}
\text{labels} & : \text{program} \rightarrow (\text{label}) \\
\text{vars} & : \text{program} \rightarrow (\text{var}) \\
\text{uses} & : \text{stmt} \rightarrow (\text{var}) \\
\text{defines} & : \text{stmt} \rightarrow (\text{var})
\end{align*}
\]

The labels function returns the set of labels in a program. The
vars function returns the set of variables used in a program (both
in expressions and as targets for assignments). The uses function
returns the set of variables used by the expressions in a statement.
The defines function returns the set of variables defined by a
statement (i.e., at most one variable – the target of the assignment).

Given a program, we define the 1-step control flow graph with
the flow function.

\[
\begin{align*}
type & \quad \text{flow} = \{\text{label } \times \text{label}\} \\
\text{flow} & : \text{program} \rightarrow \text{flow} \\
\text{flow c} & = \\text{OR} (i, s) \in c \\
\text{case s of } \text{IF } \_ \_ \_ j k \rightarrow (i, j), (i, k) \\
& \quad \_ \_ \_ \rightarrow (i, i + 1) \{i + 1 \in \text{labels c}\}
\end{align*}
\]
It says that if \( (i, s) \) is a node of the program, then if \( s \) is a conditional jump \( 1 \rightarrow j \rightarrow k \), then control can flow from \( 1 \) to \( j \), and from \( i \) to \( k \) — i.e., we add both \( (i, j) \) and \( (i, k) \) to the set of edges. Otherwise, it’s an assignment, and control flows to the next statement (i.e., we add \( (i, l + 1) \) to the set of edges).

Now, we can define liveness analysis, one of the classic “backwards” dataflow analyses. The type of live say that given a program and its flow graph, it returns a set of label/variable pairs, which determine a relation saying for each label which variables are live.

\[
\text{live : program } \rightarrow \text{flow } \rightarrow \{\text{label } \times \text{var}\}
\]

\[
\text{live code flow } =
\]
\[
\text{fix Live } \leq \text{labels code } \times \text{vars code is}
\]
\[
\bigvee ((i, stmnt) \in \text{code})
\]
\[
\bigvee ((i, v) \in \text{uses stmnt})
\]
\[
\bigvee ((i, j) \in \text{flow},
\]
\[
\{ (l, v) \in \text{Live},
\]
\[
\neg (v \in \text{? defines stmnt})\}
\]

For a statement \( \text{stmt} \) at label \( i \), we say that the variable \( v \) is live at \( i \) if \( v \) is used by \( \text{stmt} \). The variable \( v \) is also live at \( i \) if control flows from \( i \) to \( j \), and \( v \) is live at \( j \), assuming that \( \text{stmt} \) isn’t a definition site for \( v \).

When computing this analysis, again we need to use a bounded fixed point, which we do by taking the Cartesian product of the labels and variables occurring in the program.

Next, we give one of the classic forwards dataflow analyses, reaching definitions. This analysis is used to figure out whether an assignment (a “definition”) can influence the value of later expressions or not.

\[
\text{reachingDefinitions : program } \rightarrow \text{flow } \rightarrow \{\text{([label } \times \text{var}) } \times \text{label}\}
\]

\[
\text{reachingDefinitions code flow } =
\]
\[
\text{fix RD } \leq \{\text{labels code } \times \text{vars code} \} \times \text{labels code is}
\]
\[
\bigvee ((i, stmnt) \in \text{code})
\]
\[
\bigvee ((i, v) \in \text{defines stmnt})
\]
\[
\bigvee ((i, j) \in \text{flow},
\]
\[
\{ (l, v) \in \text{RD},
\]
\[
\neg (v \in \text{? defines stmnt})\}
\]

We define a function reachingDefinitions which takes a program and a set of flows as arguments, and returns the relation of type \(\{([\text{label }] \times \text{var}) \times \text{label}\} \). An entry \(\{(l, v), i\}\) in this relation means that \( v \) reaches \( i \) at label \( l \) reaches program point \( i \).

This is then computed as a fixed point of two clauses. First, if there is a definition \( v \) at program point \( i \), then \( v \) is reached by that definition. Second, if \( l, v \) reaches \( j \), and \( j \) flows to \( i \), then \( l, v \) reaches \( i \) as long as \( v \) is not re-defined at \( i \).

As Whaley et al. [2005] observed, Datagol makes it very easy to express dataflow analyses, and it is similarly easy in Datafun.

4. Type System

Datafun’s typing judgment \( \Delta; \Gamma \vdash e : A \) is defined by the inference rules given in Figure 3. We gloss \( \Delta; \Gamma \vdash e : A \) as follows: “expression \( e \) has type \( A \) using variables from \( \Delta \cup \Gamma \)”, and moreover the value of \( e \) is monotone with respect to the variables in \( \Gamma \).

The context \( \Delta \) types discrete variables; \( \Gamma \), monotone variables. Both admit the usual structural rules of exchange, weakening, and contraction. Variables from either context may be used freely (rules \( \text{VAR}, \text{VAR}' \)).

For clarity, we also give typing rules for our syntax sugar, in Figure 3. These use the auxiliary judgments \( \Delta; \Gamma \vdash p : A \Rightarrow \Delta ' \), which can be read as saying that “in the contexts \( \Delta \) and \( \Gamma \), the pattern \( p \) typechecks at type \( A \), binding the variables in \( \Delta ' \); and

\( \Delta; \Gamma \vdash L \Rightarrow \Delta ' \), which says that “in the contexts \( \Delta \) and \( \Gamma \), the comprehension clauses in \( L \) bind the variables in \( \Delta ' \)”.

4.1 Functions and Application

Two function types require two function introduction rules: the discrete \( \lambda \) and the monotone \( \lambda^+ \). These simply introduce variables into their respective contexts. Monotone function application \( \text{APP}^+ \) is perfectly standard, but discrete function application \( \text{APP} \) has a peculiarity: the argument \( e_2 \) gets an empty monotone context.

To understand why, recall our gloss: the application \( e_1, e_2 \) must be monotone in \( \Gamma \). But \( e_1 \) is a discrete, and in general non-monotone, function \( \Delta \rightarrow B \); there is no guarantee that it respect any order on its argument. (Suppose, for example, \( e_2 \) were some monotone variable \( x : A \in \Gamma \).) We work around this scoff-law behavior on \( e_1 \)’s part by ensuring its argument \( e_2 \) is constant with respect to \( \Gamma \)—which we accomplish by simply prohibiting \( e_2 \) from using any of \( \Gamma \)’s variables.

This technique of wiping clean the monotone context to guarantee constancy of a subterm recurs in several other rules. Readers familiar with linear logic’s! comonad [Girard 1987] or with judgmental formulations of modal logics of necessity [Pfenning and Davies 2001] may notice a feeling of déjà vu; indeed, there is a hidden comonad at work here. But we are getting ahead of ourselves. For more on that, turn to Section 5.

4.2 Products and Sums

The pairing and projection rules, \( \text{PAIR} \) and \( \pi \), are completely standard, as is the \( ! \) rule for sum introduction. Sum elimination, however, splits into two rules, \( \text{CASE} \) and \( \text{CASE}^+ \). \( \text{CASE}^+ \) requires its branches to be monotone in the variable \( x \) it introduces, and consequently its subject \( e \) is permitted access to the monotone context \( \Gamma \). CASE, however, analyses its subject \( e \) as a constant — wiping clean its monotone context — and thus is allowed to introduce the variable \( x \) into the discrete context \( \Delta \).

4.3 Booleans

While TRUE and FALSE are straightforward, there are two rules for boolean elimination, \( !f \) and \( !f^+ \). This is because in Datafun, \( 1 \) plus \( 1 \) does not equal \( 2 \); booleans are not a sum of units. At the type \( 1 + 1 \), \( \text{i11()} \) and \( \text{i12()} \) are incomparable. But in Datafun, \( 1 \rightarrow \) false. Therefore, to eliminate a boolean in a monotone fashion, one must ensure one’s then-branch is always greater than one’s else-branch.

Thus Datafun has two if rules. First, \( !f \), where the boolean \( e \) being analysed is constant (has an empty monotone context), and so the branches \( e_1, e_2 \) may be arbitrary expressions.

Second, \( !f^+ \), where the subject \( e \) has full access to \( \Gamma \), but the if-expression must have semilattice type, and the else-branch is constrained to be \( !e \) — the least value, thus smaller than \( e_1 \).

This is a conservative approach: there are many semantically monotone, but untypeable, \( ! \)-terms. However, it is complete for semilattice types, for in that case (if \( e \) then \( e_1 \) else \( e_2 \)) may be rewritten \( (e_2 \lor e \in \text{case}(e_2 \lor e \in \text{case}(e_1 \lor e)) \); as long as \( e_1 \geq e_2 \) and so \( e_2 \lor e_1 = e_1 \), this will not change the meaning of the expression, only (potentially) its execution efficiency.

Thus the only meaningful restriction here is to semilattice types. In practice, we have yet to find a case where this is problematic.

---

1. Wherever we write “constant” in this section, substitute “constant with respect to the monotone context.” The discrete context is never “wiped clean”, and behaves entirely as it would in a simply-typed \( \lambda \)-calculus.

2. For simplicity, we have omitted the unit type \( ! \) from our presentation of Datafun, but it is easy enough to imagine including it.
4.4 Semilattices and Sets

The semilattice $\varepsilon$ and $\vee$ operations are typed by the rules of the same name. As $\vee$ is monotone, its arguments have full access to the monotone context $\Gamma$.

Recall that sets are ordered by inclusion: although $2 \subseteq 3$, nonetheless $[2] \not\subseteq [3]$. For this reason the rule $\{\}$ for constructing a singleton set $\{e\}$ wipes clean its element $e$’s monotone context. Datafun does not need empty-set or union operators, since $\varepsilon$ and $\vee$ generalize them.

Finally, we come to $\vee$, the set-comprehension rule. This rule has the flavor of a monadic “bind” operation, but generalized to a result of any semilattice type. This operation is naturally monotone both in the set $e_1$ being iterated over and in the expression $e_2$ which we are taking the least upper bound of. Since sets are ordered by inclusion regardless of the ordering on their elements, $e_2$ is not required to be monotone in the variable $x$.

4.5 Fixed Points

The reason Datafun tracks monotonicity is to permit taking fixed-points of monotone functions. $\text{FIX}$ expresses exactly that. As mentioned in Section 2, however, it is limited to types of the form $\downarrow_{\text{fin}}$ finite semilattice eotypes.

$\text{FIX}_\leq$ loosens this restriction by letting us take fixed points at (not-necessarily-finite) semilattice eotypes $\downarrow_{\text{fin}}$ as long as we provide an upper bound $\varepsilon_1 : \downarrow_{\text{fin}}$ which we can check we do not exceed.

5. Denotational Semantics

We give a denotational semantics for Datafun in terms of three categories (Set, Poset, and SemiLat) and two adjunctions between them (see Figure 7). We present the notation we use in Figure 8; we take care to distinguish between sets and posets, and since posets are more central to our semantics, most of our notation concerns them. We take less care to distinguish posets and semilattices, since while a set can be partially ordered in many ways, a poset either is or is not a semilattice.

5.1 The Category SemiLat

SemiLat is the category of join-semilattices with least elements, which we call simply “semilattices”.

Directly, a semilattice is a poset $L$, with a least element $\varepsilon$, in which any two elements $a, b$ have a least-upper-bound $a \vee b$.

\[ x : A \in \Delta \quad \frac{\text{VAR}}{\Delta ; \Gamma \vdash x : A} \]

\[ \Delta, \Gamma ; x : A \vdash e : B \quad \frac{\text{VAR}}{\Delta, \Gamma \vdash x : A} \]

\[ \Delta, \Gamma \vdash \lambda x . e : A \rightarrow B \quad \frac{\lambda}{\Delta, \Gamma \vdash \lambda x . e : A \rightarrow B} \]

\[ \Delta, \Gamma \vdash e_1 : A \quad \frac{\Delta, \Gamma \vdash \Delta \quad \frac{\Delta, \Gamma \vdash e_2 : B}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A}} \]

\[ \Delta, \Gamma \vdash e : A_1 \quad \frac{\Delta, \Gamma \vdash \Delta \quad \frac{\Delta, \Gamma \vdash e : A_2}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A_1 \times A_2}} \]

\[ \Delta, \Gamma \vdash e : A \rightarrow B \quad \frac{\Delta, \Gamma \vdash e_1 : A_1 \quad \frac{\Delta, \Gamma \vdash e : A \rightarrow B}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A}} \]

\[ \Delta, \Gamma \vdash \Delta \quad \frac{\Delta, \Gamma \vdash \lambda x . e : A \rightarrow B}{\Delta, \Gamma \vdash \lambda x . e : A \rightarrow B} \]

\[ \Delta, \Gamma \vdash e_1 : A_1 \quad \frac{\Delta, \Gamma \vdash \Delta \quad \frac{\Delta, \Gamma \vdash e_2 : A_2}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A_1 \times A_2}} \]

\[ \Delta, \Gamma \vdash e_1 : A \rightarrow B \quad \frac{\Delta, \Gamma \vdash e_2 : A \rightarrow B}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A} \]

\[ \Delta, \Gamma \vdash e_1 : A \rightarrow B \quad \frac{\Delta, \Gamma \vdash e_2 : A \rightarrow B}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A} \]

\[ \Delta, \Gamma \vdash e_1 : A_1 \quad \frac{\Delta, \Gamma \vdash \Delta \quad \frac{\Delta, \Gamma \vdash e_2 : A_2}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A_1 \times A_2}} \]

\[ \Delta, \Gamma \vdash e_1 : A \rightarrow B \quad \frac{\Delta, \Gamma \vdash e_2 : A \rightarrow B}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A} \]

\[ \Delta, \Gamma \vdash e_1 : A \rightarrow B \quad \frac{\Delta, \Gamma \vdash e_2 : A \rightarrow B}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A} \]

\[ \Delta, \Gamma \vdash e_1 : A \rightarrow B \quad \frac{\Delta, \Gamma \vdash e_2 : A \rightarrow B}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A} \]

\[ \Delta, \Gamma \vdash e_1 : A \rightarrow B \quad \frac{\Delta, \Gamma \vdash e_2 : A \rightarrow B}{\Delta, \Gamma \vdash e_1 \cdot e_2 : A} \]
Lemma 2. The denotation $[\mathbf{L}]_\mathbf{sa}$ denoted by a finite eqtype $\mathbf{sa}$ is finite.

Second, to show that bounded fixed-points $(\text{fix } x \leq e_\top)$ is $e$ terminate, we need any possible $e_\top$ to pick out a finite-height subposet:

Lemma 4. (Fixed points in finite-height pointed posets) Any monotone map $f : P \to P$ on a poset $P$ of finite height with a least element $\epsilon$ has a least fixed point of the form $f^0(\epsilon)$.

Proof. Consider the sequence $\epsilon, f(\epsilon), f^2(\epsilon), f^3(\epsilon), \ldots$. Note that $\epsilon \leq f(\epsilon)$, so by monotonicity of $f$ and induction $f^i(\epsilon) \leq f^{i+1}(\epsilon)$. Thus this sequence forms an ascending chain. Since $P$ has finite height, this chain cannot be infinite; thus there is an $n$ such that $f^n(\epsilon) = f^{n+1}(\epsilon)$, i.e., $f^n(\epsilon)$ is a fixed-point of $f$.

Now consider any fixed-point $x$ of $f$. Since $\epsilon \leq x$, by monotonicity of $f$, induction, and $x = f(x)$, we have $f^n(\epsilon) \leq x$. Thus $f^n(\epsilon)$ is the least fixed point of $f$.  

We write $(\text{fix } f \in L)$ for the least fixed point of a monotone map $f$ on a semilattice $L$ of finite height.

5.4 Metatheory

We have proven the following theorems:

Theorem 1 (Weakening and exchange), The rules

\[
\begin{align*}
\Delta; \Gamma \vdash e : A &\quad \text{WEAK} & \Delta_2, \Delta_1 ; \Gamma_2, \Gamma_1 \vdash e : A \\
\Delta, \Gamma \vdash e : A &\quad \text{XCHG} & \Delta_1, \Delta_2 ; \Gamma_1, \Gamma_2 \vdash e : A
\end{align*}
\]

are admissible.

Theorem 2 (Substitution, discrete). From

- $\Delta; \vdash e_1 : A$
- and $\Delta, x : A ; \Gamma \vdash e_2 : B$

it follows that

- $\Delta; \Gamma \vdash [e_1/x] e_2 : B$
- and $[[e_1/x] e_2] \delta \gamma = [e_2] \delta [e_1] \delta \gamma$

Theorem 3 (Substitution, monotone). From

- $\Delta; \Gamma \vdash e_1 : A$
- and $\Delta, x : A ; \Gamma \vdash e_2 : B$

it follows that

- $\Delta; \Gamma \vdash [e_1/x] e_2 : B$
- and $[[e_1/x] e_2] \delta \gamma = [e_2] \delta [e_1] \delta \gamma$

5.5 Discussion

It has been known for a very long time that database queries have a monadic structure arising from the adjunction between $\text{Set}$ and $\text{SemiLat}$ — indeed, the very name of the Kleisli database system was chosen to reflect this fact!

However, our decomposition of this adjunction into two smaller adjunctions, with an intermediate way-station in $\text{Poset}$ is new. By interpreting our types in the intermediate category $\text{Poset}$, we gain access to the comonad $\text{Disc} [A]$. This lets us distinguish between...
Derivation                  Denotation

\[ [\Delta; \Gamma \vdash e : A] \in \text{Set}(||\Delta||, \text{Poset}(||\Gamma||, [A])) \]

\[
\begin{align*}
\Gamma, x : A &\vdash e : B \\
\Delta, \Gamma &\vdash \lambda x. e : A \to B \\
\delta_y &= \pi_t \delta \\
\end{align*}
\]

\[
\begin{align*}

\Delta, \Gamma &\vdash \text{fix } x \leq e_1 \text{ is } e_2 : L \\
\delta_y &= \text{lfp} (x \mapsto [e_2] \delta \gamma \text{ if it's } \leq [e_1] \delta \gamma \text{ otherwise } [e_1] \delta \gamma) \in [L] \\
\end{align*}
\]

Figure 10. Denotations of Datafun typing derivations
We consider the denotational semantics to be primary in Datafun; as with Datalog, any implementation technique is valid so long as it lines up with these semantics. As a proof of concept, however, we present a simple call-by-value structural operational semantics in Figure 11 and show that all well-typed terms terminate. In our operational semantics we:
1. Assume all semilattice operations ($\epsilon$, $\lor$, $\lor$, and $\fix$) are subcribed with their type.
2. Drop the distinction between discrete and monotone variables, and write $x, y$ for arbitrary variables.
3. Add iter expressions, which occur as intermediate forms in the evaluation of $\fix$.
4. Classify some expressions $e$ as values $v$, and add a value-form $\{v\}$ for finite sets.

We use a small-step operational semantics using evaluation contexts $E$ after the style of Felten and Hieb (1992) to enforce a call-by-value evaluation order; an evaluation context $E$ is an expression with a hole ($[]$) in it (written $[]$)) such that whatever is in the hole is next in line to be evaluated (if it is not a value already). To fill the hole $[]$ in an evaluation context $E$ with the expression $e$, we write $E[e]$.

We define a relation $e \mapsto e'$ for expressions $e$ whose outermost structure is immediately reducible; we extend this relation to all expressions with the rule $e \mapsto e'$. In our rules for $e \mapsto e'$ where $e$ is an iter expression we make use of a decidable ordering test on values, $v \subseteq u : A$, and a corresponding equality test $v \equiv u : A$. We define these using inference rules, but they are easily seen to be decidable by induction on $A$. The quantifiers in the premise of the rule $\subseteq$ range over finite domains, and thus pose no issue.

### 6.1 Computing fixed Points via iteration

Our implementation strategy for $\fix x$ is $e$ is exactly that suggested by the proof of Lemma 4, starting from $e$, iteratively apply $\lambda x.e$ until a fixed point is reached.

To model this iteration, we introduce iter forms into our syntax. The fixed point expression $\fix E \cdot m \cdot n \cdot x \cdot e$ is immediately steps to the form $\iter_{m,n}(e_1; x; e')$, which can be thought of as an initial state of the iteration, starting with $e_1$.

The intuition for iterating to the fixed point is that we apply the body and then check to see if the result changed. This is why we also introduce the two-place version $\iter_{m,n}(v_1; e_2; x; e')$ which remembers the old value $v_1$, so that we can test it against $e_2$ (when it reaches a value $v_2$) to determine whether we’ve reached a fixed point. If not, we can continue to iterate from $v_2$ with $\iter_{m,n}(v_2; x; e')$.

The $\iter_{m,n}$ forms are similar, but additionally check that the iteration value never exceeds their first argument, to implement the clamping behavior of $\fix x \leq e$.

### 6.2 A Logical Relation for Termination

To prove that all well-typed terms terminate according to our operational semantics, we use a logical relations argument.

The standard approach of interpreting each type as a partial equivalence relation (PER) on closed terms turns out not to be sufficient in our case, and we need to extend it to prove termination. Just as posets are sets equipped with an order structure, we define our semantic types as PERs equipped with a preorder respecting the PER structure. The intuition is that since we needed the order structure in the denotational semantics to prove the definedness of fixed points, we similarly need an order structure on the syntax to prove the termination of fixed points. Therefore, we inductively define relations $a \sqsubseteq b \mid A$ for each type $A$, then show how to understand these relations as preordered PERs.

As a matter of notation, $a, b, c$ range over closed expressions; $\gamma, \sigma$ over substitutions containing only closed expressions; and $\Ctx(\Gamma)$ is the set of all substitutions of closed expressions for the variables in $\Gamma$.

Because it simplifies our definitions and proofs, we introduce an additional pseudo-type $\Box A$, which orders $A$ discretely, $x \leq y \iff x = y$.

### Types

$$A ::= \ldots \mid \Box A$$

This represents the Disc $\{\cdot\}$ comonad on Poset present in our denotational semantics. Observe that under this interpretation $A \rightarrow B$ is just $\Box A \rhd B$. In particular, if we let $\Box A = \Disc \{A\}$ then $[A \rightarrow B] = [\Box A \rhd B] = \Disc [[A]] \Rightarrow [B]$.

We define the following relations:

$$\begin{align*}
a & \subseteq b \mid A & \text{definition given below} \\
\gamma & \subseteq \sigma \mid \Gamma & \text{iff } \forall x : A \mid \Gamma. \gamma(x) \subseteq \sigma(x) \mid A \\
\Gamma & \vdash e_1 \subseteq e_2 \mid A & \text{iff } \forall (\gamma_1 \subseteq \gamma_2 \mid \Gamma). \gamma_1(e_1) \subseteq \gamma_2(e_2) \mid A \\
\gamma_1, e_1 & \subseteq \gamma_2, e_2 \mid A & \text{may be seen as a transitive square:} \\
\gamma_1(e_1) & \subseteq \gamma_1(e_2) \\
\gamma_2(e_1) & \subseteq \gamma_2(e_2)
\end{align*}$$

As a matter of notation, for any relation $Y \subseteq Z \mid X$, we write:

$$\begin{align*}
Y & \subseteq Z \mid X & \text{iff } Y \subseteq Z \mid X \land Z \subseteq Y \mid X \\
Y & \mid X & \text{iff } Y \subseteq Y \mid X
\end{align*}$$

We now give the definition of $a \sqsubseteq b \mid A$ by induction on $A$.

$$\begin{align*}
a & \subseteq b \mid \Box A & \text{iff } a \equiv b \mid A \\
a & \subseteq b \mid 2 & \text{iff } a \rightarrow^* v \lor b \rightarrow^* u \lor v \subseteq u : 2 \\
a & \subseteq b \mid (A) & \text{iff } a \rightarrow^* [v_1] \lor b \rightarrow^* [v_2] \\
& \lor \forall v_1. \exists u_1. (v_1 \equiv u_1 \mid A) \\
a & \subseteq b \mid A_1 + A_2 & \text{iff } a \rightarrow^* \inf_1 v \lor b \rightarrow^* \inf_1 u \lor v \subseteq u : A_1 \\
a & \subseteq b \mid A_1 \times A_2 & \text{iff } a \rightarrow^* (v_1, v_2) \lor b \rightarrow^* (u_1, u_2) \\
& \lor \forall v. (v_1 \equiv u_1 \mid A_1) \\
a & \subseteq b \mid A \rightarrow B & \text{iff } a \subseteq b \mid \Box A \rhd B \\
a & \subseteq b \mid A \rightarrow B & \text{iff } a \rightarrow^* \lambda x. e_1 \lor b \rightarrow^* \lambda x. e_2 \\
& \lor (x : A \rightarrow e_1 \subseteq e_2 : B)
\end{align*}$$

It may not be immediately obvious that (for a given $A$) the relation $a \subseteq b \mid A$ can be seen as a preordered PER. This requires the following two theorems, proven by induction on $A$:

**Theorem 4** (Partial reflexivity). If $a \subseteq b \mid A$ then $a \subseteq a \mid A$ and $b \subseteq b : A$. 
Theorem 7 (Termination).

If $a \subseteq b \mid A$ and $b \subseteq c \mid A$, then $a \subseteq c \mid A$.

From these it follows immediately that $a \equiv b \mid A$ is a PER, and $a \sqsubseteq b \mid A$ forms a preorder over this PER which respects it.

Theorem 6 (Termination). If $a \mid A$ then $a \overset{\rightarrow}{\Rightarrow} v$.

Proof. By cases on the definition of $a \subseteq a \mid A$.

Theorem 7 (Fundamental theorem). If $\Delta; \Gamma \vdash e : A$ then $\square \Delta; \Gamma \vdash a \mid A$.

Proof. By induction on $\Delta; \Gamma \vdash e : A$; full proof available at https://github.com/rntz/datafun/

It follows as immediate corollary of termination and the fundamental property that every closed, well-typed program terminates.

7. Comparing Datalog and Datafun

At this point, we have demonstrated by example that Datafun programs are rather similar to Datalog programs, and we have given the typing and denotational semantics of Datafun. However, we still need to explain why our semantics lets us express Datalog-style programs.

To understand this, recall that Datalog is a bottom-up logic programming language. A program consists of a primitive database of facts, along with a set of rules the rules the programmer wrote. A Datalog program executes by using the rules to derive new conclusions from the database, and extending the database with them, until no additional conclusions can be drawn. Then the query can be checked simply by seeing if it occurs in the final database.

This is, essentially, a fixed point computation – each stage of execution of a Datalog program takes a database and returns an extended database, until a fixed point is reached. The stratified negation restriction essentially ensures that the database transformer defined by a Datalog program is a monotone function on the set of
facts. This is why the type system of Datafun tracks the monotonicity of functions — since we permit both higher-order definitions and taking fixed points, we need to ensure that the body of a fixed point definition is monotone in order to guarantee that the recursion is well-founded.

This ensures that the recursive definition is well-defined, but is not sufficient by itself to guarantee termination. To manage this, Datalog depends upon the other two restrictions described in the introduction. By restricting terms occurring in predicates to consist of either atoms or variables, Datalog ensures that quantifiers need only be instantiated with the atoms used in a program. By requiring every variable in the consequent of rules to also occur in the premise of a rule, it ensures that every consequent will also only feature atoms occurring in the original program.

Then, since there can only be finitely many atoms in a finite program, this means that the set of possible arguments to a predicate is itself finite. Then the lattice of sets of atomic predicates ordered by inclusion will be finite, and so fixed point iteration is guaranteed to terminate.

Instead of this (rather indirect) scheme, Datafun directly tracks the finiteness of types, permitting recursion only if it is over a finite type, or is bounded explicitly. These two approaches achieve the same effect, albeit in different ways. Datalog’s approach has the benefit that no type discipline is needed to ensure finiteness. One advantage of our choice is that we permit recursion over any semilattice, not just the semilattice of sets. A much more serious advantage of our approach is that it makes it much easier to write fixed-point computations which actually compute with the data they see (for example, the CYK parser we wrote computed lengths of substrings).

8. Implementation

We have built a proof-of-concept implementation of Datafun in Racket, available at https://github.com/rntz/datafun/. In addition to core Datafun, it supports pattern-matching, variant types, record types, dictionaries, subtyping, antitone functions, and unbounded (potentially nonterminating) fixed points. We implement everything in an naïve style, and perform no optimizations.

Type inference As a practical matter, type-checking needs to distinguish between discrete and monotone λ application, case, let, and if. In our implementation we solve this in two ways:

1. Bidirectional type inference (Pierce and Turner 2000) determines whether As and applications are discrete or monotone.
2. For if, case, and let, the programmer annotates which form is intended; for example, (if e then e₁ else e₂) is written (when e then e₁) to indicate the rule if₁ applies.

We believe that this scheme could be extended to support polymorphism in the style of Danield and Krishnaswami (2013). However, it would not be an entirely off-the-shelf affair, since we would want to add support for polymorphism over the tones of function, so that, for example, \( \lambda \alpha . \lambda x . f \) x can be assigned the principal type \( \forall \alpha : \text{tone}. \forall x : \alpha . f \alpha x \). A tone may be empty (for a discrete function) or \( + \) for a monotone function.

9. Related and Future Work

Aggregation Aggregation of values — for example, taking the sum \( \sum_{x \in A} f x \) of a function \( f \) across a set \( A \) — is a useful and ubiquitous database operation. Datafun naturally supports semilattice aggregation via \( \lor \), but many natural operations such as summation do not form semilattices on their underlying type.

There are several potential ways to add support for aggregations to Datafun:

- Common aggregations can be provided as primitive functions, for example size : \( \langle A \rangle \rightarrow \mathbb{N} \) or sum : \( \langle A \rightarrow \mathbb{N} \rangle \rightarrow \langle A \rangle \rightarrow \mathbb{N} \).
- In the style of Machiavelli (Ohori et al. 1989), one could add a general operator hom : \( B \rightarrow \langle A \rightarrow B \rightarrow \mathbb{B} \rangle \rightarrow \langle A \rangle \rightarrow B \), which effectively linearizes a set in an unspecified order. The semantics of hom are, alas, necessarily nondeterministic.
- One could augment Datafun with a type of bags (multisets) \( A^* \): bags naturally support a much broader class of aggregation — commutative monoids — than sets. See, for example, Rudu and Plotkin (2014) and Gibbons et al. (2015).

Optimization Because Datalog is so strongly constrained, there has been a lot of very successful work on optimizing it, ranging from compilation into binary decision diagrams (Bryant 1992) by Whaley et al. (2005), to the famous “magic sets” (Bancilhon et al. 1986) algorithm.

From our perspective, magic sets are a natural next step for investigation into how to optimize Datafun. Intuitively, the magic sets algorithm exploits the fact that Datalog (as a total logic language) has both a top-down and bottom-up reading, and rewrites the program so that it does bottom-up search, while using top-down reasoning to strategically avoid adding useless facts to the database. Transplanting this analysis to Datafun would essentially give us optimized implementations of fixed points, but extending the magic sets algorithm is likely to be very subtle, since Datafun has higher-order functions and Datalog does not. As a result, our goal is to first see if magic sets can be applied to first-order Datafun programs, and then use defunctionalization (Reynolds 1998) to extend it to full Datafun.

Very recently, Madsen et al. (2016) have introduced the Flix language, which extends the semantics of Datalog to support defining relations valued in arbitrary lattices (rather than just the powerset of atoms). Like Datafun, this lets Flix support using monotone functions (on suitable lattices) in program expressions. Unlike Datafun, Flix does not yet have monotonicity checking for programmer-defined operators. However, because Flix does not extend Datalog to higher order, efficient Datalog implementation strategies (such as semi-naive evaluation) continue to apply.

Databases Datalog has sometimes been described as “relational algebra plus fixed points”, and there is a long line of work on embedding database query languages into general-purpose languages, including pioneering efforts such as Machiavelli (Ohori et al. 1989) and Kleisli (Wong 2000), as well as more recent systems such as Ferry (Grust et al. 2009) and LINQ in C# (Cheney et al. 2013). The focus of this work has been on embedding query languages based on relational algebra into general purpose languages, with an emphasis on statically compiling higher-order queries into the first-order queries supported by existing database systems (Cheney et al. 2014) is a representative example).

Our approach is a little bit different. Instead of embedding Datalog into a general purpose language, Datafun is also a “little language”, albeit one that happens to be a higher-order functional language. We very deliberately did not try to embed Datafun into an existing language, because that would have greatly complicated the context-management operations needed to ensure monotonicity.

In fact, from a language designer’s perspective, Datafun can be seen as an argument in favor of extending functional languages to support programming with user-defined, non-strong comonads.

Deletion Ganzinger and McAllester (2002) showed how forward-chaining logic programming permits concise and elegant expression of a wide variety of algorithms, including a natural cost semantics. However, they noted that there were some algorithms (such as union-
find and greedy algorithms) which could be formulated in this style, if
there were additionally support for deleting facts from a database. Later,
Simmons and Fleming (2009) went on to show how deletion could be
given a logical interpretation by formulating in terms of linear logic
programming.

This naturally raises the question of whether we could identify a
“linear Datafun” corresponding to this style of programming, where
we might extend types to model features like deletion. There are
many nontrivial semantic issues (e.g., how to define monotonicity),
but it seems promising question for future work.

Termination Datafun as presented is Turing-incomplete. This is
advantageous for optimization; for example, one powerful opti-
mization technique is loop reordering (in SQL terminology, join
reordering), that is, taking advantage of the equation
\[ \forall x \in e_1 \forall y \in e_2 \exists e = \forall(x \in e_1) \exists(y \in e_2) e \]
when \( x, y \notin \text{FV}(e_1) \cup \text{FV}(e_2) \). But this equation does not always
hold in the presence of nontermination; for example, if \( e_1 = \_e \) and \( e_2 \) diverges.

Nonetheless, without adding advanced facilities for termination
checking, there are many functions it is difficult to implement
without use of general recursion. So a natural direction for future
work is to study how to add support for general recursion to Datafun.
Because domains (Abramsky and Jung 1994) can be understood as
partial orders with directed joins, there are likely many interesting
categorical structures connecting the category of domains to the
category of posets, some of which will hopefully lead to a principled
type-theoretic integration of partial functions into Datafun.

User-Defined Posets and Semilattices The two fundamental semi-
lattice types Datafun provides are booleans and sets; products and
functions merely preserve semilattice structure where they
find it. One might contemplate allowing the programmer to de-
fine their own semilattice structures using something like Haskell’s
newtype/instance. In general, this is a difficult problem, because
we may need to do serious mathematical reasoning to prove that
a comparison function implements a partial ordering, or that a
datatype can be equipped with a semilattice structure obeying this
partial ordering which is commutative, associative and idempotent.

One example of such a family of types are the lexicographic
sum types. Given two posets \( P \) and \( Q \), their disjoint union \( P + Q \) is
also a poset, with left values compared by the \( P \)-ordering, and right
values compared by the \( Q \)-ordering, and no ordering between left
and right values. However, this is not the only way that the disjoint
union could be equipped with an order structure.

For example, we could define the lexicographic sum \( P \sqcup Q \),
which has the same elements as the sum, but extending the coproduct
order relation with the additional facts that \( \text{in}_1(p) \leq \text{in}_2(q) \). Indeed,
we already have a special case of this: as we noted earlier, our
boolean type is not \( 1+1 \), but it is \( 1<1 \).

But as our Booleans already show, giving good syntax for their
eliminators is difficult, because we have to show that not just a term
is monotone, but that the different branches of a lexicographic case
expression are ordered with respect to each other. For the case of
ordered Booleans, we were able to give a special eliminator which
guaranteed it, but it is still requires proof.

One natural direction for future work is to extend the syntax of
Datafun with support for these kinds of proofs, perhaps taking
inspiration from dependent type theory.

Acknowledgments

Thank you to:

• Chris Martens, for helpful feedback and discussion on connec-
tions to logic programming.
• The anonymous ICFP reviewers, for pointing out areas which
were previously unclear or incomplete.
